Abstract

The literature on excess return prediction has considered a wide array of estimation schemes, among them unrestricted and restricted regression coefficients. We consider bootstrap aggregation (bagging) to smooth parameter restrictions. Two types of restrictions are considered: positivity of the regression coefficient and positivity of the forecast. Bagging constrained estimators can have smaller asymptotic mean-squared prediction errors than forecasts from a restricted model without bagging. Monte Carlo simulations show that forecast gains can be achieved in realistic sample sizes for the stock return problem. In an empirical application using the data set of Campbell, J., and S. Thompson (2008): “Predicting the Equity Premium Out of Sample: Can Anything Beat the Historical Average?”, Review of Financial Studies 21, 1511-1531, we show that we can improve the forecast performance further by smoothing the restriction through bagging.

Keywords: Constraints on predictive regression function; Bagging; Asymptotic MSE; Equity premium; Out-of-sample forecasting; Economic value functions.

JEL Classification: C5, E4, G1.

1 Introduction

We study bootstrap aggregation (bagging) methods to improve the out-of-sample prediction of a simple univariate linear model (following Campbell and Thompson [CT], 2008) for the equity premium by imposing restrictions in the regression. In imposing restrictions, such as positivity of the regression coefficient, or positivity of the prediction, usually the coefficient or prediction is simply set to zero if the estimated value is negative. This amounts to the application of an indicator function. Bühlmann and Yu (2002) showed that bagging can reduce the variance of the estimator in this situation by “smoothing” the indicator function. In this paper we show in theory, through simulations, and in an empirical application using the same data set as CT (2008), that bagging coefficient and forecast restrictions can improve the predictive power of a linear model.

Excess returns prediction has attracted academics and practitioners for many decades since the early 1920s, when Dow (1920) studied the role of dividend ratios as a possible predictor for returns. In the 1980s, a number of authors presented empirical evidence of ex-post (in-sample) return predictability. Fama and Schwert (1977), Fama and Schwert (1981), Rozeff (1984), Keim and Stambaugh (1986), Campbell (1987), Campbell and Shiller (1988a,b) and Fama and French (1988, 1989) showed that excess returns could be successfully predicted based on lagged values of variables such as dividend-price ratio and dividend yield, earnings-price ratio and dividend-earnings ratio, interest rates and spreads, inflation rates, book-to-market ratio, volatility, investment-capital ratio, consumption, wealth, and income ratio, and aggregate or net equity issuing activity.

Subsequent work, however, demonstrated that these results do not hold during the bull market period of the 1990s; see Lettau and Ludvigson (2001) or Schwert (2002). For example, during this period when stock prices soared, the dividend yield systematically drifted downwards, thus generating negative sample correlation between returns and dividend yield, contrary to the positive historical correlation. Furthermore, since early results concerned only ex-post predictability, they were of little practical interest. Studies of ex-ante (out-of-sample) return predictability have found either that previous successful results were restricted to particular sub-samples (Pesaran and Timmermann 1995) or that return predictability was a statistical illusion; see Bossaerts and Hillion (1999). In addition, several authors pointed out that the apparent predictability of stock returns might be spurious as many of the predictor variables were highly persistent, leading to
possibly biased coefficients and incorrect \( t \)-tests in predictive regressions; see, for example, Nelson and Kim (1993), Cavanagh, Elliot, and Stock (1995), and Stambaugh (1999). These problems are exacerbated when large numbers of variables are considered and only results that are apparently statistically significant are reported; see Foster, Smith, and Whaley (1997) and Ferson, Sarkissian, and Simin (2003).

The inconclusive evidence has inspired the use of time-varying regression models. As pointed out by Pesaran and Timmermann (2002) and Timmermann (2007) “forecasts of stock returns face a moving target that is constantly changing over time. Just when a forecaster may think that he has figured out how to predict returns, the dynamics of market prices will, in all likelihood, have moved on, possibly as a consequence of the forecaster’s own efforts.” On the other hand, alternative econometric methods were advocated for correcting the above mentioned bias and conducting valid inference: for example Cavanagh, Elliot, and Stock (1995), Mark (1995), Kilian (1999), Ang and Bekaert (2006), Jansson and Moreira (2006), Lewellen (2004), Torous, Valkanov, and Yan (2004), Campbell and Yogo (2006), and Polk, Thompson, and Vuolteenaho (2006).

More recently, Goyal and Welch (2008) argued that none of the conventional predictor variables proposed in the literature seems capable of systematically predicting stock returns out-of-sample. Their empirical evidence suggests that most models were unstable or spurious, and most models are no longer significant even in-sample. The authors show that the earlier apparent statistical significance was especially confined to the years of the Oil Shock of 1973–1975; see also Butler, Grullon, and Weston (2006).

Our approach is motivated by CT (2008), who show that many predictive regressions outperform the historical average return forecast once a restriction is imposed on the sign of the coefficient in the regression. Imposing a constraint on the coefficient amounts to applying shrinkage estimation. Shrinkage methods are designed to reduce estimator variance at the possible cost of incurring bias. CT (2008) find out-of-sample predictive power of the common stock return predictors over the historical average. The advantage is small (not statistically significant) but nonetheless economically meaningful for mean-variance investors. We impose these a-priori parameter restrictions (which we call CT restrictions) in a regression function of equity premium conditional on various predictors, then we smooth the restrictions by bagging (Bühlmann and Yu, 2002, and Inoue and
Kilian, 2008). The resulting bagging forecast has lower variance than the forecast using the CT restricted estimator. Whether mean-squared forecast error (MSFE) is also reduced in the process depends on how much bagging increases bias. We explore this question in simulations and in an application to the same data set used in CT (2008).

After bagging an indicator-type restriction as it is imposed in CT (2008), the resulting asymptotic shape of the estimator follows the cumulative distribution function of a normal random variable (Bühlmann and Yu, 2002, Proposition 2.1). That is, instead of taking one value (say, zero) on one side of the restriction, and a positive value on the other side of the restriction, undergoing an abrupt transition, the estimator now transitions smoothly from one side of the restriction to the other. See, in particular, Figure 1 in Bühlmann and Yu (2002). Thereby, bagging provides another perspective on non-linear, smoothly transitioning estimators as pioneered in, for example, Teräsvirta (1994, 2006).

The paper is organized as follows. In Section 2 we review bagging and present the bagging approach to restricted parameter estimation. In Section 3, we present a Monte Carlo simulation. Section 4 describes the data set and presents empirical results. Section 5 concludes.

2 Bagging restrictions on regression functions

A linear model assumes that the regression function \( \mathbb{E}(y|X) \) is linear in the predictors \( X = (x_1, \ldots, x_k)' \). When \( k \) is small, such as \( k = 1 \), we may have good reason to believe that the coefficient of \( X \) must be positive or must exceed some known value. In that case, we may use the a-priori belief to shrink the parameter space. Such a-priori beliefs are less intuitive when \( k \) is large, so we restrict the consideration to the case \( k = 1 \). A simple method is to use a hard-thresholding indicator function to define a constrained least squared estimator \( \bar{\beta} = \max(\tilde{\beta}, 0) = \tilde{\beta} \cdot 1(\tilde{\beta} > 0) \) with \( \tilde{\beta} \) being an unconstrained least squares estimator of \( \beta \). By shrinking the parameter space for the slope coefficient of \( x_1 \) in the prediction model towards zero, one reduces the variance, and possibly the overall mean squared forecast error, at the cost of bias. While imposing such a constraint can improve the predictive power of the linear model if the constraint is correct, the restricted estimator \( \bar{\beta} \) involves a discontinuous hard-threshold indicator (jump) function at the boundary of the constrained parameter space. We show that we can further improve the predictive ability of
the constrained linear model by smoothing the indicator function using bagging. We consider two
types of restrictions as considered in CT (2008), namely positivity of the forecast, motivated by the
requirement that the mean of the equity premium should be positive, and positivity of the regression
coefficient, motivated by simple insights from financial theory, for example that the dividend
yield should have a positive influence on the equity premium.

Goyal and Welch (GW 2008) show that predictive regressions cannot beat the historical average.
Campbell and Thompson (CT 2008), on the other hand, show that many predictive regressions beat
the historical average, once constraints are imposed. Consider

$$y_{t+1} = \alpha + \beta x_t + u_{t+1}, \quad t = 1, \ldots, T,$$

where $y$ is the excess return on the S&P500 over the 3-month T-bill interest rate. The regressor $x_t$
stands for a predictor variable such as dividend yield, earnings yield, book-to-market ratio, return
on equity, long-term government bond yield, term spread, default spread, inflation rate, equity
share of new issues, etc. GW find that forecasts from the unrestricted model

$$\tilde{y}_{n+1} = \tilde{\alpha}_n + \tilde{\beta}_n x_n$$

(with $\tilde{\alpha}_n, \tilde{\beta}_n$ unrestricted OLS) are worse than forecasts with the exclusion restriction $\beta = 0$, which
amounts to the historical average (HA) $\frac{1}{n} \sum_{t=1}^{n} y_t$. CT show that the positivity constraint $\beta > 0$
produces a better forecast than the exclusion restriction. In this paper we aim to show that bagging
can further improve the CT constrained forecast.

2.1 Bagging

Bootstrap aggregating, or bagging, means to estimate a parameter on each of a set of $J$ subsamples
drawn from the original data set $D$ and then average over the $J$ estimates. As $J \to \infty$, the bagged
estimator will differ from the estimator obtained from the entire data set $D$ only if it is a nonlinear
or adaptive estimator (Hastie, Tibshirani, and Friedman, 2001, p. 246). An estimator is said to be
“unstable” if a small change in the training set will lead to a significant change in the estimator
(Breiman, 1996). In our application to an indicator function, the bagged predictor smoothes the
instability caused by estimation and model uncertainty and the hard threshold function.

The mechanism of bagging has been explained in various ways, for example Breiman (1996)
under squared-error loss and Lee and Yang (2006) under convex loss (e.g., a tick function for
quantiles). Bühlmann and Yu (2002) show that for a nonsmooth unstable predictor, bagging
reduces variance of the first order term. In particular, they show that bagging can reduce the mean-squared forecast error by averaging over the randomness of variable selection. Buja and Stuetzle (2006) and Friedman and Hall (2007) expand a smooth unstable function into linear and higher order terms, and show bagging reduces the variance of the higher order terms. Grandvalet (2004) argues that bagging stabilizes prediction by equalizing the influence of training samples. Stock and Watson (2012) show that bagging is asymptotically equivalent to Bayesian shrinkage. Applications of bagging include inflation (Inoue and Kilian 2008), financial volatility (Hillebrand and Medeiros 2010), equity premium (Huang and Lee 2010), short-term interest rates (Audrino and Medeiros 2011), and employment data (Rapach and Strauss 2007).

To fix notation, let

\[ D_t = \{(Y_s, X_{s-1})\}_{s=t-R+1}^t \quad (t = R, \ldots, T) \]

be a training set at time \( t \) and let \( \varphi(X_t, D_t) \) be a forecast of \( Y_{t+1} \) or of the binary variable \( 1(Y_{t+1} \geq 0) \) using this training set \( D_t \) and the explanatory variable vector \( X_t \). The optimal forecast \( \varphi(X_t, D_t) \) for \( Y_{t+1} \) will be the conditional mean of \( Y_{t+1} \) given \( X_t \) if we have the squared error loss function, or the conditional quantile of \( Y_{t+1} \) on \( X_t \) if the loss is a tick function as in Koenker and Basset (1978).

Suppose each training set \( D_t \) consists of \( R \) observations generated from the underlying probability distribution \( P \). The forecast \( \{\varphi(X_t, D_t)\}_{t=R+1}^T \) can be improved if more training sets can be generated from \( P \) and if the forecast can be formed from averaging the multiple forecasts obtained from the multiple training sets. Ideally, if \( P \) were known and multiple training sets \( D_t^{(j)} \) \((j = 1, \ldots, J)\) could be drawn from \( P \), an ensemble aggregating predictor \( \varphi_A(X_t) \) could be constructed by averaging of \( \varphi(X_t, D_t^{(j)}) \) with respect to \( P \), i.e.,

\[ \varphi_A(X_t) = \mathbb{E}_P \varphi(X_t, D_t), \]

where \( \mathbb{E}_P (\cdot) \) denotes expectation with respect to \( P \), and the subscript \( A \) in \( \varphi_A \) denotes “aggregation.”

In practice, \( P \) is not known. We may estimate \( P \) by its empirical distribution, \( \hat{P}(D_t) \), for a given data set \( D_t \). Then, from the empirical distribution \( \hat{P}(D_t) \), multiple subsamples \( D_t^* \) can be drawn by an appropriate bootstrap method. The question which bootstrap algorithms can provide consistent densities for moment estimators and quantile estimators in time series settings is addressed, for example, in Hall, Horowitz, and Jing (1995) and Fitzenberger (1997). Bagging predictors, \( \varphi^B(X_t, D_t^*) \),
can then be computed by averaging over the subsamples. More specifically, the bagging predictor \( \varphi^B(X_t, D^*_t) \) can be obtained following the steps: (1) Given a training set of data at time \( t \), \( D_t = \{(Y_s, X_{s-1})\}^t_{s=t-R+1} \), construct the \( j \)th bootstrap sample \( D^{*(j)}_t = \{(Y^{*(j)}_s, X^{*(j)}_{s-1})\}^t_{s=t-R+1} \), \( j = 1, \ldots, J \), according to the empirical distribution of \( \hat{P}(D_t) \) of \( D_t \). (2) Compute the bootstrap predictor \( \varphi^{*(j)}(X_t, D^{*(j)}_t) \) from the \( j \)th bootstrapped sample \( D^{*(j)}_t \). (3) Compute the bagging predictor \( \varphi^B(X_t, D^*_t) \) by averaging over \( J \) bootstrap predictors
\[
\varphi^B(X_t, D^*_t) = \frac{1}{J} \sum_{j=1}^{J} \varphi^{*(j)}(X_t, D^{*(j)}_t).
\]

2.2 Bagging Restrictions

In the context of a simple univariate regression, we let
\[
\varphi(x_t, D_t) = E(y_{t+1}|x_t) = \alpha + \beta x_t,
\]
where \( D_t = \{(y_{s+1}, x_s)\}^t_{s=t-R+1} \) for \( t = R, \ldots, T \).

The two types of restrictions considered in CT (2008) are positivity of the coefficient \( \beta \) (PC) and positivity of the forecast \( \varphi(x_t, D_t) \) (PF). We compare the following forecasts:

1. **HA** (Historical Average forecast with exclusion restriction \( \beta = 0 \)):
\[
y_{T+1}^{HA} = \frac{1}{T} \sum_{t=T-R+1}^{T} y_t.
\]

2. **UF** (Unrestricted Forecast):
\[
y_{T+1}^{UF} = \tilde{\alpha}_T + \tilde{\beta}_T x_T
\]
where \( \tilde{\alpha}_T, \tilde{\beta}_T \) are unrestricted OLS estimators. UF is used in Goyal and Welch (2008).

3. **PC** (forecast with Positive Coefficient restriction \( \beta > 0 \)):
\[
y_{T+1}^{PC} = \bar{\alpha}_T + \bar{\beta}_T x_T,
\]
where \( \bar{\beta}_T = \max\{\tilde{\beta}_T, 0\} = 1(\tilde{\beta}_T > 0) \tilde{\beta}_T \), and \( \bar{\alpha}_T = 1(\tilde{\beta}_T > 0) \tilde{\alpha}_T + 1(\tilde{\beta}_T \leq 0) y_{T+1}^{HA} \). PC is used in CT (2008).
4. **PC-GH** (forecast with Positive Coefficient restriction $\beta > 0$ using bagging as in Gordon and Hall (GH), 2009):

\[
y^{\text{PC-GH}}_{T+1,J} = \frac{1}{J} \sum_{j=1}^{J} \left( y_{T+1}^{\text{PC,*}(j)} \right) = \hat{\alpha}_{T,J} + \hat{\beta}_{T,J} x_T, \tag{3}
\]

where $\hat{\beta}_{T,J} = \frac{1}{J} \sum_{j=1}^{J} \tilde{\beta}_{T,(j)}$ and $\hat{\alpha}_{T,J} = \frac{1}{J} \sum_{j=1}^{J} \tilde{\alpha}_{T,(j)}$. As $J \to \infty$, $\hat{\beta}_{T,J}$ converges to $E^*\beta_T$, $\hat{\alpha}_{T,J}$ converges to $E^*\alpha_T$, and $y^{\text{PC-GH}}_{T+1,J}$ converges to $E^*(y_{T+1}^{\text{PC}})$, where $E^*$ denotes expectation with respect to the empirical distribution $\hat{P}(D_T)$.

5. **PF** (forecast with Positive Forecast restriction $\varphi(x_t, D_t) > 0$):

\[
y^{\text{PF}}_{T+1} = 1 \left( y_{T+1}^{\text{UF}} > 0 \right) y_{T+1}^{\text{UF}}.
\]

6. **PF-GH** (forecast with Positive Forecast restriction $\varphi(x_t, D_t) > 0$ using bagging as in GH 2009):

\[
y^{\text{PF-GH}}_{T+1,J} = \frac{1}{J} \sum_{j=1}^{J} \left( y_{T+1}^{\text{PF,*}(j)} \right),
\]

where again there is convergence $\lim_{J \to \infty} y^{\text{PF-GH}}_{T+1,J} = E^*(y_{T+1}^{\text{PF}})$, where $E^*(\cdot)$ denotes expectation with respect to the empirical distribution $\hat{P}(D_T)$.

With this notation, we can rephrase the aim of this paper. Comparative statements can be understood in the mean-square error sense, but we also consider two alternative loss functions in the empirical exercise: GW (2008) find that unrestricted forecasts $y_{n+1}^{\text{UF}} = \tilde{\alpha}_{n} + \tilde{\beta}_{n} x_n$ (with $\tilde{\alpha}_{n}, \tilde{\beta}_{n}$ OLS estimators) are worse than HA forecasts (with exclusion restriction $\beta = 0$). CT (2008) show that PC and PF produce better forecasts than HA. We will show that PC-GH and PF-GH further improve PC and PF.

The reason for this improvement is the following equivalence that is motivated by the second equality in (3).

**Proposition 1.** Bagging the positive coefficient forecast $y_{T+1}^{\text{PC}}$ is equivalent to computing the forecast $y_{T+1,J}^{\text{PC-GH}}$ from the Gordon and Hall (2009) bagging estimators $\hat{\alpha}_{T,J}, \hat{\beta}_{T,J}$. That is,

\[
\frac{1}{J} \sum_{j=1}^{J} y_{T+1}^{\text{PC,*}(j)} = y_{T+1,J}^{\text{PC-GH}}.
\]
Proof.

\[ \frac{1}{J} \sum_{j=1}^{J} y_{T+1}^{PC,*} = \frac{1}{J} \sum_{j=1}^{J} (\tilde{\alpha}_{T}^{*}(j) + \tilde{\beta}_{T}^{*}(j) x_T) = \left( \frac{1}{J} \sum_{j=1}^{J} \tilde{\alpha}_{T}^{*}(j) \right) + \left( \frac{1}{J} \sum_{j=1}^{J} \tilde{\beta}_{T}^{*}(j) \right) x_T = \hat{\alpha}_T + \hat{\beta}_T x_T = y_{T+1}^{PC-GH}. \]

Even though Proposition 1 is a very simple insight, it provides a powerful reason, in view of Breiman (1996), why bagging the coefficient estimates and obtaining \( y_{T+1}^{PC-GH} \) can improve the PC constrained forecast \( y_{T+1}^{PC} \) used in CT (2008).

### 2.3 AMSE Comparison

With our objective in view, we compare the asymptotic mean-square error (AMSE) of the unrestricted, the restricted, and the bagging estimator and forecast. Keeping the decomposition of MSE into variance and bias in mind, we show that under certain circumstances, bagging estimators and forecasts have a shrinkage advantage over simple constrained estimators and forecasts as used in CT (2008). That is, their reduction in variance outweighs their increase in bias. For this purpose, we collect some results from the literature, in particular from Bühlmann and Yu (2002) and from Gordon and Hall (2009), and express them in a unified framework.

Let \( \theta \) denote either a prediction \( \varphi(x_t, D_t) \) from a regression or the parameter vector \( (\alpha, \beta) \). The unrestricted estimator \( \tilde{\theta}_T \) is, thus,

\[ \tilde{\theta}_T = \tilde{\alpha}_T + \tilde{\beta}_T x_T, \text{ or } \tilde{\theta}_T = (\tilde{\alpha}_T, \tilde{\beta}_T). \]

The restricted estimator for \( \theta \) subject to a lower bound \( \theta_1 \) is

\[ \tilde{\theta}_T = \max\{\tilde{\theta}_T, \theta_1\}. \]

The Gordon and Hall (GH, 2009) bagging estimator is

\[ \hat{\theta}_T = \lim_{J \to \infty} \frac{1}{J} \sum_{j=1}^{J} \max\{\tilde{\theta}^{*}(j), \theta_1\} = \lim_{J \to \infty} \frac{1}{J} \sum_{j=1}^{J} \tilde{\theta}^{*}(j) = \mathbb{E}(\max\{\tilde{\theta}^{*}, \theta_1\} | D_T) \]

for the situation where a lower bound \( \theta_1 \) is known. As before, \( D_T \) is the available data set at time \( T \), \( D_T^{*} \) is a bootstrap sample, and \( \tilde{\theta}^{*} \) is a bootstrap replication of \( \tilde{\theta}_T \) from \( D_T^{*} \). There are \( J \) such bootstrap replications; expectation statements hold for \( J \to \infty \); in practice \( J \) is of course finite.

We use the moving block bootstrap method for subsampling.
Consider the case where $\theta$ is the regression coefficient $\beta$. Let the data-generating process be

$$y_{t+1} = \alpha_0 + \beta_0 x_t + u_{t+1},$$

where $\mathbb{E}(u_t) = 0$, $\mathbb{V}(u_t) = \sigma_u^2 < \infty$. Let the data-generating slope parameter be of a local-to-threshold form

$$\beta_0 = \beta_1 + b\sigma \bar{T}^{-1/2}. \tag{4}$$

Here, $\beta_1$ is the threshold applied in the constraint. For example, in the equity premium application where the hypothesis of predictability is studied against a null of no predictability, $\beta_1 = 0$. Note that the term “data-generating” then refers to the choice of hypotheses and does not make a statement about financial economics. Equation (4) does not make a statement whether or not returns are asymptotically predictable. If a researcher wanted to study the base case of some predictability rather than no predictability, they would specify a non-zero $\beta_1$, possibly of a parametric form derived from financial economic theory.

The estimated model is a simple linear regression of $y_{t+1}$ onto $x_t$, and the estimators under consideration are the OLS estimator $\tilde{\beta}_T$ of UF, the simple PC constrained estimator

$$\tilde{\beta}_T = \max \left\{ \tilde{\beta}_T 1 \left( \tilde{\beta}_T > \beta_1 + c\sigma \bar{T}^{-1/2} \right), \beta_1 \right\} = \max \left\{ \tilde{\beta}_T 1 \left( \sqrt{T} \tilde{\beta}_T / \sigma > c \right), \beta_1 \right\},$$

and the bagging estimator PC-GH

$$\hat{\beta}_T = \frac{1}{J} \sum_{j=1}^{J} \tilde{\beta}_{T}^{(j)} = \frac{1}{J} \sum_{j=1}^{J} \max \left\{ \tilde{\beta}_{T}^{(j)} 1 \left( \sqrt{T} \tilde{\beta}_{T}^{(j)} / \sigma > c \right), \beta_1 \right\}.$$

In this setup, $c$ is a critical value that the scaled and studentized difference between the estimator and the threshold value $\beta_1$ has to exceed before the estimator is adopted over the threshold value. In Bühlmann and Yu (2002) and in Gordon and Hall (2009) one finds the following results on the asymptotic distributions of the estimators and their dependence on the data-generating perturbation $b$ and on the critical decision value $c$.

**Proposition 2.** [Bühlmann and Yu (2002), Gordon and Hall (2009)]

Let $Z \sim \mathcal{N}(0,1)$, $\Phi(\cdot)$ the cumulative distribution function and $\phi(\cdot)$ the probability density function.
of the standard normal distribution. Then, as $T \to \infty$,

\[ \sqrt{T} \sigma_{\beta}^{-1}(\hat{\beta}_T - \beta_1) \xrightarrow{d} Z + b. \]  
(5)

\[ \sqrt{T} \sigma_{\bar{\beta}}^{-1}(\bar{\beta}_T - \beta_1) \xrightarrow{d} (Z + b) 1(Z + b - c > 0). \]  
(6)

\[ \sqrt{T} \sigma_{\hat{\beta}}^{-1}(\hat{\beta}_T - \beta_1) \xrightarrow{d} (Z + b) \Phi(Z + b - c) + \phi(Z + b - c). \]  
(7)

The positive coefficient (PC) constraint in (2) means that $c = 0$ and $\beta_1 = 0$. For this case, we compare the asymptotic mean-squared error (AMSE) of the limiting random variables in (5), (6), and (7) of Proposition 2. Equation (7) also shows that the bagging estimator is a smoothly transitioning sigmoid function.

**Asymptotic bias (Abias):** For all $z \in \mathbb{R}$, note that

\[ z + b \leq (z + b) 1(z + b > 0) < (z + b) \Phi(z + b) + \phi(z + b), \]

which results in the following order of the asymptotic biases:

\[ \text{Abias of } \hat{\beta}_T \leq \text{Abias of } \bar{\beta}_T < \text{Abias of } \hat{\beta}_T, \]

where

\[ \text{Abias of } \hat{\beta}_T = \mathbb{E}(Z + b) - b = 0, \]

\[ \text{Abias of } \bar{\beta}_T = \mathbb{E}[(Z + b) 1(Z + b > 0)] - b, \]

\[ \text{Abias of } \hat{\beta}_T = \mathbb{E}[(Z + b) \Phi(Z + b) + \phi(Z + b)] - b. \]

Therefore, Abias gets worse as we impose the restriction and as we add bagging. For example, when $b = 0$,

\[ \text{Abias of } \hat{\beta}_T = \mathbb{E}(Z) = 0, \]

\[ \text{Abias of } \bar{\beta}_T = \mathbb{E}[Z 1(Z > 0)] = 0.5\sqrt{2/\pi} \approx 0.3989, \]

\[ \text{Abias of } \hat{\beta}_T = \mathbb{E}[Z \Phi(Z) + \phi(Z)] = \pi^{-1/2} \approx 0.5642. \]

**Asymptotic variance (Avar):** While Abias increases, asymptotic variance is reduced by imposing a restriction and more so by bagging the restriction. For $b = 0$, the asymptotic distribution
of the simple constrained estimator $\beta_T$ is a standard normal truncated to the positive half-line and thus has asymptotic variance $\mathbb{V}(Z_1(Z > 0)) = (1 - 1/\pi)/2 = 0.3408$. The Avar of the bagging estimator is $\mathbb{V}(Z\Phi(Z) + \phi(Z)) = 1/3 + \sqrt{3}/(2\pi) - 1/\pi = 0.2907$. AMSE($\hat{\beta}_T$) = 0.6088 and AMSE($\hat{\beta}_T$) = 0.4998 are substantially smaller than AMSE($\hat{\beta}_T$) = 1. Note that the ratio AMSE($\hat{\beta}_T$)/AMSE($\hat{\beta}_T$) = 1.2181. The AMSE of PC-GH is worse due to much larger Abias($\hat{\beta}_T$). However, the case $\beta = 0$ (i.e., $b = 0$) is not an interesting one. We impose the restriction $\beta > 0$ (i.e., $b > 0$). For other values of $b$, analytical evaluations are difficult and we use numerical evaluation. The results for some grids of $b$ on $[-2, 4]$ are presented in Table 1.

**AMSE Comparison:** Summarizing the results of Table 1, we note the following observations.

1. When $\beta > 0$ (i.e., $b > 0$), if we impose the correct restriction $\beta > 0$, we can improve AMSE. For example, when $b = 1$ in Table 1, AMSE($\hat{\beta}_T$)/AMSE($\hat{\beta}_T$) = 0.85. Hence PC-GH reduces AMSE by 15% from PC. When $b = 2$, AMSE($\hat{\beta}_T$)/AMSE($\hat{\beta}_T$) = 0.8943, and thus PC-GH is about 11% better than PC.

2. When $\beta \gg 0$ (i.e., $b \gg 0$), if we impose the obvious restriction $\beta > 0$, we do not gain much. For example, when $b = 3$ in Table 1, the restriction is hardly binding and the gain is small. Bagging makes a minor contribution for AMSE($\hat{\beta}_T$)/AMSE($\hat{\beta}_T$) = 0.9698. When the restriction becomes even more obviously correct with $b = 4$, the gain becomes even smaller. PC is the same as UF in AMSE. PC-GH is only slightly better than PC with AMSE($\hat{\beta}_T$)/AMSE($\hat{\beta}_T$) = 0.9955.

3. When $\beta \ll 0$ (i.e., $b \ll 0$), if we impose the wrong restriction $\beta > 0$, then the increase in Abias dominates the reduction in Avar. AMSE substantially deteriorates by imposing the wrong constraint and more so by bagging the constraint as can be seen from Table 1 for $b = -1$ or $-2$.

**3 Simulation**

**Simulation design:** In order to evaluate the performance of the restricted and bagging predictors, we construct a simulation experiment that is motivated by the stock-return prediction problem.
First, we generate \( \{ w_t \}_{t=1}^{T=200} \) from

\[
w_t = \rho w_{t-1} + e_t, \quad e_t \sim NID \left( 0, \sigma_e^2 \right), \quad \sigma_e = 0.2,
\]

where \( \rho \in \{0, 0.5, 0.9, 0.99\} \) setting different levels of persistence of the regressor. Next, we let \( x_t = \exp(w_t)/\text{std}(\exp(w_t)) \) so that \( \{ x_t \} \) be positive to mimic the predictor variables that we will consider in the equity premium prediction in Section 4. The predictor \( x \) is normalized with the standard deviation \( \text{std}(\cdot) \). Then, we generate \( \{ y_t \}_{t=1}^{T=200} \) from

\[
y_t = 0.02 + \beta x_{t-1} + u_t, \quad u_t \sim NID \left( 0, \sigma_u^2 \right), \quad \mathbb{E}(u_t e_s) = 0, \forall t, s,
\]

where \( \sigma_u \in \{0.1, 1\} \). The data-generating value of \( \beta \) deviates from the bound \( \beta_1 \) by the local drift parameter \( b \) with rate \( T^{-1/2} \), i.e., \( \beta = \beta_1 + b \sigma \beta T^{-1/2} \). We set the values of \( \beta_1, \sigma_\beta, \) and \( b \) as follows:

\[
\beta_1 = 0, \quad \sigma_\beta^2 = \sigma_u^2 \left( \sum_{t=1}^{100} (x_t - \bar{x})^2 \right)^{-1}, \quad \text{and } b \in \{1, 3, 5, 10, 15, 20, 30, 50, 100\}.
\]

We use the first half of the total 200 to estimate \( \beta \) using the unrestricted, restricted, and the bagging (PC-GH) estimators. The PC-GH estimator is computed over \( J = 200 \) bootstrap samples. Using each of the above estimators at time \( t = 100, \ldots, 199 \), we compute the unrestricted, restricted, and bagging forecasts \( \theta_{t+1}(x_t) \) of \( y_{t+1} \). The forecasts over the second half of observations are compared with the actual value \( y_{t+1} \). We compute the following out-of-sample predictive ability measure of each model

\[
100 \cdot R^2_{\text{OS}} = 100 \left( 1 - \frac{1}{100} \sum_{t=101}^{200} \left( y_t - \theta_t(x_{t-1}) \right)^2 \right),
\]

where the historical average \( \bar{\theta}_t^{\text{HA}} = \frac{1}{100} \sum_{s=t-100}^{t-1} y_s \) (for \( t = 101, \ldots, 200 \)) is taken as a benchmark forecast as in CT (2008). The same statistic \( 100 \cdot R^2_{\text{OS}} \) was used in CT (2008) to compare various forecast models. We repeat the steps above over 1000 Monte Carlo replications and compute the average of the out-of-sample \( 100 \cdot R^2_{\text{OS}} \).

**Simulation results:** In this simulation, unlike in the empirical application to equity premium prediction, the unrestricted forecast UF always dominates HA by construction of the simulation design with \( b > 0 \). Hence, it is not interesting to compare the forecasts with HA for this simulation section as we do it in the empirical section. Here we present the gain in \( 100 \cdot R^2_{\text{OS}} \) over the unrestricted forecast UF from imposing a constraint and from bagging. Figures 1-2 report this gain, defined as

\[
\text{Gain-in-} R^2 = (100 \cdot R^2_{\text{OS}})_{\text{model}} - (100 \cdot R^2_{\text{OS}})_{\text{UF}}, \quad (8)
\]
where \( model = PC, PC-GH, PF, \) or \( PF-GH. \) Each of Figures 1-2 reports the gain in \( R^2 \) for two different values of \( \sigma_u. \) The four panels of each figure show the situation for one of the four different values of \( \rho. \) In each panel, the abscissa shows the different values of \( b, \) and the ordinate shows the gain as defined in (8) for that specific 3-tuple \( (\sigma_u, \rho, b). \) Summarizing, we make the following observations.

1. For a wide range of \( b, \) the gains over UF from imposing the PC constraint and PF constraint are positive.

2. For a wide range of \( b, \) bagging further improves the constrained forecasts. PC is further improved by PC-GH, and PF is further improved by PF-GH.

3. The gains from the PF constraint is smaller when \( \sigma_u \) is smaller (Figure 1) than when \( \sigma_u \) is larger (Figure 2), indicating that the PF constraint may be more useful when the market becomes more volatile.

4. Note that high persistence (high \( \rho \)) leads to a large value of \( \sum_{t=1}^{100} (x_t - \bar{x})^2 \) and thus reduces \( \sigma_\beta, \) which reduces the local drift \( (b \sigma_\beta T^{-1/2}) \) from the bound. Therefore, for higher \( \rho, \) the effects of the constraint or of bagging are bigger for a given value of \( b, \) and the effects are present over a larger range of \( b. \)

4 Let’s Do It Again: Equity Premium Prediction

4.1 Data and Constraints

**Data:** We use the data set of Campbell and Thompson (2008), which was kindly provided by Sam Thompson. The data frequency is monthly; the sample period is 1871-2005. Excess returns on the S&P 500 are calculated from the returns time series (1871M2 through 2005M12, CRSP since 1927) and the 3-month Treasury-Bill interest rate (denoted as \( r_f \), 1920M1 through 2005M12, 1870M2 through 1919M12 calculated following Goyal and Welch (2008)). The predictor variables are the dividend yield \( d/p \) (1872M2 through 2005M12), earnings yield \( e/p \) (1872M2 through 2005M12), smoothed earnings yield \( se/p \) following Campbell and Shiller (1988b), Campbell and

\footnote{The effect of the persistence (measured by \( \rho \)) in the predictor \( x \) of the predictive regression on the finite sample estimation bias in \( \beta \) has been widely studied since the seminal paper by Stambaugh (1999). Examples are Valkanov (2003), Lewellen (2004), Campbell and Yogo (2006), and Zhu (2013). In that context it is interesting to observe the effect of the persistence \( \rho \) on gains from using the constraint and bagging, which is examined here from Figures 1-2.}
Shiller (1998) (1881M1 through 2005M12), book-to-market ratio $b/m$ (1926M6 through 2005M12), smoothed return on equity $roe$ as described in Campbell and Thompson (2008) (1936M6 through 2005M12), the 3-month Treasury-Bill $tbl$ (1920M1 through 2005M12), long-term government bond yield $lty$ (1870M1 through 2005M12), the term spread $ts$, i.e. the difference between long-term and short-term treasury yields (1920M1 through 2005M12), the default spread $ds$, i.e. the difference between corporate and Treasury bond yields (1919M1 through 2005M12), the lagged inflation rate $inf$ (1871M5 through 2005M12), and the equity share of new issues $nei$ proposed by Baker and Wurgler (2000). See Table 2 for a summary.

**Comparing out-of-sample predictive ability:** For the prediction exercise presented in this section, we use the estimation sample periods and forecast periods as shown in Table 2, which are the same as in Campbell and Thompson (2008). We take the “recursive scheme” that uses expanding windows for estimating models. We move the estimation window forward by one month to estimate the models. We keep rolling the estimation sample forward until the last one-month ahead forecast is made for the month of 2005M12.

**Constraints:** We apply sign restrictions on the coefficients $\beta$ depending on the predictor and a positivity restriction on the forecast $y_{t+1}$ of the risk premium, as well as a combination of these two. The coefficient restrictions for the different predictors are listed in Table 2; they are the same as in CT (2008). We impose the hard constraint and we apply bagging to smooth it. This results in the following set of forecasts: UF, PC, PF, PCF (applying positivity on coefficient and forecast jointly), PC-GH, PF-GH, and PCF-GH (bagging the joint restriction).

**4.2 Empirical results**

We compare the prediction performance in terms of three criteria. Table 3 compare MSFE in $100 \cdot R^2_{OS}$ proposed by CT (2008). Table 4 modifies the $100 \cdot R^2_{OS}$ with the adjustment in MSFE of Clark and West (2006). Table 5 reports the utility function of an investor with simple mean-variance preferences $U = \text{expected portfolio return} - \frac{\gamma}{2} \text{portfolio variance}$ as proposed by CT (2008).
4.2.1 Comparing MSFE in $100 \cdot R^2_{OS}$ of CT (2008)

Table 3 presents the results that are directly related to Goyal and Welch (2008) and Campbell and Thompson (2008). The reported numbers are out-of-sample $R^2$ statistics $R^2_{OS}$ multiplied by 100.

$$100 \cdot R^2_{OS} = 100 \left( 1 - \frac{1}{P} \sum_{t=T-P+1}^T (y_t - \theta_t (x_{t-1}))^2 \right),$$

where $P$ denotes the number of out-of-sample forecasts, $\theta_t (x_{t-1})$ is the prediction from the UF, PC, PF, PCF, PC-GH, PF-GH, and PCF-GH model, respectively. These models are organized in the columns of Tables 3 through 5. The rows of the tables show the different univariate predictors that are used for $x$, from dividend yield $d/p$ through new issues $nei$. There are 11 such predictors.

The last row reports a simple, equally weighted, combined forecast from all 11 individual forecasts. The first reported numbers in Table 3 are out-of-sample statistics $100 \cdot R^2_{OS}$. The second reported numbers in parentheses are the values of statistics to test the null hypothesis that MSFE gain is zero.\(^2\)

We note the following observations from Table 3.

1. Positive values of $100 \cdot R^2_{OS}$ indicate that a model is better than HA. Many values of $100 \cdot R^2_{OS}$ in Table 3 are negative, indicating that it is not easy to beat the historical average. However, many of these values become larger or turn positive when the PC, PF, or PCF constraints are imposed. The values of statistics tend to get larger as well when the constraints are imposed even if none of them are significantly positive.

2. The constraints work. Many of the eleven PC forecasts are better than the unconstrained forecast. 10 of 11 PCs are at least as good as UF. All 11 PFs are at least as good as UFs. So are all 11 PCFs.

3. Bagging works for 7 of 11 cases when PC is compared to PC-GH, for 7 of 11 cases when PF is compared to PF-GH, and for 7 out of 11 when PCF is compared to PCF-GH.

\(^2\)Assuming that the estimation sample is finite while we let $P \to \infty$, we can apply Giacomini and White (2005). Then the Diebold-Mariano statistic is asymptotically standard normal under the null that $\lim_{P \to \infty} P^{-1/2} \sum_{t=T-P+1}^T E (\hat{\varepsilon}_{0,t+1}^2 - \hat{\varepsilon}_{1,t+1}^2) = 0$ where the subscript 0 denotes the HA model and the subscript 1 denotes any of the other models, which may nest the HA model. In this case we are not testing for the null hypothesis that $E (\hat{\varepsilon}_{0,t+1}^2 - \hat{\varepsilon}_{1,t+1}^2) = 0$. Instead we are testing for the null hypothesis that $\lim_{P \to \infty} P^{-1/2} \sum_{t=T-P+1}^T E (\hat{\varepsilon}_{0,t+1}^2 - \hat{\varepsilon}_{1,t+1}^2) = 0$ using the estimated forecast errors. We thank a referee for pointing this out.
4. In general CF produces the best forecast in each column, dominating all individual forecasts in most of the 7 columns. This is observed in Table 3 (but not in Tables 4, 5). Bagging works for PC and PCF constraints, as seen from pair-wise comparing the numbers in the last row. It is interesting to note that none of the MSFE gains are significantly positive in rows 1-11, but all of the CFs in rows significantly positive with all the t statistics over 2.00. The statistics are even larger with bagging.

In summary, it is hard to beat HA with UF, but imposing the constraints and bagging can improve UF. Many constrained and bagged predictions outperform HA. Combined forecasts (CF) outperform HA for all constrained models and bagging further improves the forecast power.

4.2.2 Adjusted \( 100 \cdot R^2_{OS} \) of Clark and West (2006)

Campbell and Thompson write in CT (2008, p. 1515, footnote 5) that “Clark and West (2006) point out that if the return series is truly unpredictable, then in a finite sample the predictive regression will on average have a higher mean squared prediction error because it must estimate an additional coefficient. Thus, the expected out-of-sample \( R^2 \) under the null of unpredictability is negative, and a zero out-of-sample \( R^2 \) can be interpreted as weak evidence for predictability. We do not pursue this point here because, like Goyal and Welch (2007), we ask whether predictive regressions or historical average return forecasts have delivered better out-of-sample forecasts, not whether stock returns are truly predictable.” Following these lines, we have studied (in Table 3) whether the constrained or bagged predictive regressions can beat HA, but we have not studied whether stock returns are truly predictable by using various predictors \( x \).

As suggested by Campbell and Thompson (2008) we use the out-of-sample \( R^2_{OS} \) in (9), which compares the MSFE \( \frac{1}{P} \sum_{t=T-P+1}^{T} (y_t - \theta_t (x_{t-1}))^2 \) of a predictive regression with the MSFE \( \frac{1}{P} \sum_{t=T-P+1}^{T} (y_t - \theta^HA_t)^2 \) of HA. To compare the MSFEs, the test statistics of Diebold and Mariano (1995) and West (1996) use the MSFE differential

\[
\frac{1}{P} \sum_{t=T-P+1}^{T} \left[ (y_t - \theta^HA_t)^2 - (y_t - \theta_t (x_{t-1}))^2 \right] \tag{10}
\]

to test the null hypothesis that \( E \left[ (y_t - \theta^HA_t)^2 - (y_t - \theta_t (x_{t-1}))^2 \right] = 0 \). Note that \( R^2_{OS} \) in (9), reported in Table 3, is obtained from dividing (10) by \( \frac{1}{P} \sum_{t=T-P+1}^{T} (y_t - \theta_t (x_{t-1}))^2 \).
Clark and West (CW 2006) show that when a predictive regression model (using $x$) is compared with the HA, under the null hypothesis of no predictive ability of $x$, its MSFE is expected to be greater than the HA’s MSFE. CW propose an adjustment to the MSFE differential in (10) in order to account for the disadvantage of the sample MSFE of the predictive model. The CW-adjusted MSFE differential is

$$\frac{1}{P} \sum_{t=T-P+1}^{T} \left[ (y_t - \theta_{HA}^t)^2 - \left( (y_t - \theta_t (x_{t-1}))^2 - (\theta_{HA}^t - \theta_t (x_{t-1}))^2 \right) \right]. \quad (11)$$

We use the following “CW-adjusted-$R^2_{OS}$” defined by dividing (11) by $\frac{1}{P} \sum_{t=T-P+1}^{T} (y_t - \theta_{HA}^t)^2$:

$$\text{CW-adjusted-100} \cdot R^2_{OS} = 100 \left( 1 - \frac{\frac{1}{P} \sum_{t=T-P+1}^{T} \left( (y_t - \theta_t (x_{t-1}))^2 - (\theta_{HA}^t - \theta_t (x_{t-1}))^2 \right)}{\frac{1}{P} \sum_{t=T-P+1}^{T} (y_t - \theta_{HA}^t)^2} \right).$$

Table 4 presents the CW-adjusted-100 · $R^2_{OS}$ and the test statistics in parentheses to test the null hypothesis that the MSFE gain (11) with the Clark and West adjustment is zero.\(^3\) We note the following observations.

1. Positive values of the CW-adjusted-100 · $R^2_{OS}$ indicate that a predictive regression model using $x$ is better than HA. Most values in Table 4 are positive. The numbers in Table 4 are not only larger than those in Table 3, which is by construction, but also more highly significant according to the test statistics in parentheses.

2. The constraints work, with a few exceptions for PC and PF.

3. Bagging works well for many cases for PC-GH and PCF-GH.

4. While the combined forecast (CF) is nowhere the best, it is consistently better than HA across all constraints. Bagging works for CF as in the previous tables. The combined forecast with the PC constraint is further improved by bagging (PC-GH is better), the CF with PF is further improved by bagging (PF-GH is better), and the CF with PCF is also further improved by bagging (PCF-GH is better).

4.2.3 How much $R^2$ is economically meaningful?

Although the gains from imposing constraints and bagging presented in Table 2 are small, they can be economically meaningful for mean-variance investors. As Barberis (2000) points out, “… the

\(^3\)The CW statistic of Clark and West (2006) is closely related to the ENC-T of Clark and McCracken (2001).
evidence of predictability in asset returns affects optimal portfolio choice for investors with long
horizons [...] even after incorporating parameter uncertainty, there is enough predictability in
returns to make investors allocate substantially more to stocks.” To see how gains in $R^2$ may be
translated into economic gain, following CT (2008), we consider an investor with single-period
horizon and mean-variance preferences

$$U = \text{expected portfolio return} - \frac{\gamma}{2} \text{ portfolio variance},$$

$$\quad = \mathbb{E} \left[ wy_{t+1} + \left( 1 - w \right) r^f_{t+1} \right] - \frac{\gamma}{2} \mathbb{V} \left[ wy_{t+1} + \left( 1 - w \right) r^f_{t+1} \right],$$

where $\gamma$ captures relative risk aversion. The excess return on a risky asset over the riskless interest
rate is given by $y_{t+1} = \alpha + \beta x_t + u_{t+1}$ as in (1). Following CT (2008), we assume $x_t$ has unconditional
mean zero and unconditional variance $\sigma^2_x$, and the risk-free interest rate is constantly equal to zero.
The random shock $u_{t+1}$ has unconditional mean zero and unconditional variance $\sigma^2_u > 0$. As a
result, $y_{t+1}$ has unconditional mean $\mathbb{E} (y_{t+1}) = \alpha$ and unconditional variance $\mathbb{V} (y_{t+1}) = \beta^2 \sigma^2_x + \sigma^2_u$, assuming independence of $x$ and $u$.

Without observing $x_t$, the portfolio weight in the risky asset is

$$w_0 = \frac{1}{\gamma} \frac{\mathbb{E} (y_{t+1})}{\mathbb{V} (y_{t+1})} = \frac{1}{\gamma} \frac{\alpha}{\beta^2 \sigma^2_x + \sigma^2_u},$$

and the equity premium (EP) is

$$EP_0 = \mathbb{E} \left[ w_0 y_{t+1} + \left( 1 - w_0 \right) r^f_{t+1} \right] = \frac{1}{\gamma} \frac{\alpha^2}{\beta^2 \sigma^2_x + \sigma^2_u} = \frac{1}{\gamma} \frac{\mathbb{E} (y_{t+1})^2}{\mathbb{V} (y_{t+1})} = \frac{1}{\gamma} S^2,$$

where $S$ is the Sharpe-ratio. Conditional on $x_t$, the portfolio weight in the risky asset becomes

$$w_t = \frac{1}{\gamma} \frac{\mathbb{E} (y_{t+1} | x_t)}{\mathbb{V} (y_{t+1} | x_t)} = \frac{1}{\gamma} \frac{\alpha + \beta x_t}{\sigma^2_u},$$

with EP

$$EP_1 = \mathbb{E} \left[ w_t y_{t+1} + \left( 1 - w_t \right) r^f_{t+1} \right] = \frac{1}{\gamma} \frac{\alpha^2 + \beta \sigma^2_x}{\sigma^2_u} = \frac{1}{\gamma} \frac{S^2 + R^2}{1 - R^2},$$

where $R^2 = \frac{\beta \sigma^2_x}{\beta^2 \sigma^2_x + \sigma^2_u}$. Note that $w_0$ is constant while $w_t$ is time-varying. The increase in EP from
observing $x_t$ is

$$EP_1 - EP_0 = \left( 1 + \frac{S^2}{1 - R^2} \right) \frac{1}{\gamma} R^2 > \frac{1}{\gamma} R^2.$$

The relative gain in EP is

$$\frac{EP_1 - EP_0}{EP_0} = \left( 1 + \frac{S^2}{1 - R^2} \right) \frac{R^2}{S^2} > \frac{R^2}{S^2}.$$
If $R^2$ is large w.r.t. $S^2$, then an investor can use the information in the predictive regression to obtain a large proportional increase in return. CT (2008) report $S^2 = 0.0120$ for the CT data set (monthly 1871–2005).

For example, from the bagging results, the out-of-sample $R^2_{OS}$ for dividend yield ($d/p$) of PCF-GH is 0.0016. The relative EP gain is about 13% for dividend yield as a predictor compared to the HA forecast:

$$\frac{R^2}{S^2} = \frac{0.0016}{0.0120} = 0.13 \text{ or } 13\%.$$  

Similarly, the out-of-sample $R^2_{OS}$ for earnings yield ($e/p$) of PCF-GH is 0.0024 and thus the relative EP gain is about 20% when earnings yield is used as predictor and compared to the HA forecast:

$$\frac{R^2}{S^2} = \frac{0.0024}{0.0120} = 0.20 \text{ or } 20\%.$$  

### 4.2.4 Utility function of CT (2008)

As discussed in the previous subsection CT (2008) show the economic significance of numerically small $R^2$’s by interpreting them relative to the squared Sharpe ratio. Rapach, Strauss and Zhou (2010) use the investor utility value in (12) of CT (2008) to compare the economic values of different forecasts. We adopt the same utility function (12) to compare the seven conditional predictive regression models (UF, PC, PF, PCF, PC-GH, PF-GH, and PCF-GH) relative to HA. Table 5 reports the utility level (12) of an investor using the predictive regression over the utility level of the HA forecast.

The historical average (HA) forecast does not use $x_t$ in forecasting $y_{t+1}$. The realized average utility level for the HA forecast over the out-of-sample period is

$$\hat{U}_0 = \hat{E} \left[ w_0 y_{t+1} + (1 - w_0) r^f_{t+1} \right] - \frac{\gamma}{2} \hat{V} \left[ w_0 y_{t+1} + (1 - w_0) r^f_{t+1} \right]$$

where $\hat{E}(\cdot)$ and $\hat{V}(\cdot)$ are the sample mean and sample variance over the out-of-sample period for the portfolio return $\left[ w_0 y_{t+1} + (1 - w_0) r^f_{t+1} \right]$ that was formed using the HA forecasts of $y_{t+1}$.

The seven conditional forecasts use a predictor $x_t$ in forecasting $y_{t+1}$. The realized out-of-sample average utility level for each of these forecasts is

$$\hat{U}_1 = \hat{E} \left[ w_1 y_{t+1} + (1 - w_1) r^f_{t+1} \right] - \frac{\gamma}{2} \hat{V} \left[ w_1 y_{t+1} + (1 - w_1) r^f_{t+1} \right],$$
where $\hat{\mathbb{E}}(\cdot)$ and $\hat{\mathbb{V}}(\cdot)$ are the out-of-sample sample-mean and sample-variance of the return $\left[w_t y_{t+1} + (1 - w_t)r^f_{t+1}\right]$ on the portfolio that was formed for each of the seven conditional forecasts for a given predictor. Table 5 then repeats this exercise for each of the 11 predictors considered and for the equally-weighted, combined forecast (CF) and reports the gains in utility $(\hat{U}_1 - \hat{U}_0)$ from the conditional forecasts over the utility $\hat{U}_0$ of the HA forecast. We set $\gamma = 3$; this value is commonly employed in the literature. The results with $\gamma = 2, 4$ are qualitatively similar. We note the following observations.

1. Positive values of the utility gain $(\hat{U}_1 - \hat{U}_0)$ indicate that a model is better than HA. While there are negative values for some predictors, the incidence of negative values is lower, however, than in Table 3. Even some unrestricted forecasts take positive values.\(^4\)

2. The PC and PF constraints do not work well without bagging. Without bagging only 1 PC out of 11 are better than UF. Without bagging the PF constraint does not work for all 11 predictors. Without bagging only one PCF out of 11 is better than UF.

3. Bagging works for the both PC and PF constraints: 10 PC-GH out of 11 are better than UF, 9 PF-GHs are better than UF, and 10 PCF-GH out of 11 are better than UF.

4. For CF in row 12, all CFs are positive, beating HA. The PC constraint seems to be more effective than the PF constraint. Bagging improves on CF for PC and PCF forecasts but not for PF. This is similar to Tables 3 and 4 in MSFE.

In summary, in terms of the utility level, bagging the constraints can improve the forecast. Combined forecasts (CF) outperform HA for all constrained models and bagging further improves their forecast power, as in Tables 3 and 4.

5 Conclusions

The vast literature on equity return prediction has considered a wide array of models and methods. CT (2008) propose restrictions on the regression coefficient or on the return prediction. Their

\(^4\)We note that recent work by McCracken and Valente (2012) can possibly be applied here to assess the statistical significance of the utility gains. They show that the difference in mean-variance utilities can be asymptotically normal despite the fact that the models are nested. Since the asymptotic variance that accounts for the effects of the parameter estimation is often difficult to estimate, they use a bootstrap proposed by Calhoun (2011).
shrinkage approach reduces MSFE by increasing the forecast bias and reducing the forecast error variance.

In this paper, we apply bagging to reduce the forecast error variance compared to simple constrained estimators at the potential cost of an increase in bias. We review the theory behind bagging, in particular Breiman (1996), Bühlmann and Yu (2002), and Gordon and Hall (2009), and explore the bias-variance trade-off and shrinkage properties of bagging in simulations. We show that for a large variety of signal-to-noise and regressor persistence scenarios, bagging can further improve predictive power as long as the imposed constraint is not completely obvious and far from binding, but, loosely speaking, true enough.

In the stock return prediction problem, we find that the constraint on the sign of the regression coefficient and/or the positivity constraint on the forecast itself improves prediction. Smoothing the hard constraint at zero for the return forecast by bagging over a large set of bootstrap replications, we improve this edge in predictive power, which we measure by the out-of-sample $R^2$ as in CT (2008), by the utility function of CT (2008) as reported in Rapach, Strauss, and Zhou (2010), and by the adjusted out-of-sample $R^2$ of Clark and West (2006). In particular after accounting for the natural MSFE-disadvantage of a regressor model compared to the historical mean under the null, the advantage of bagging constraints becomes very clear. Simple combination forecasts do consistently well, but not always best. In our application, they could also be improved by bagging.
References

Figure 1. Gains in $100 \cdot R^2_{\text{OS}}$ from imposing constraint and bagging over UF when $\sigma_u = 0.1$

Notes: The gain of a model in $100 \cdot R^2_{\text{OS}}$ over UF is $(100 \cdot R^2_{\text{OS}})_{\text{model}} - (100 \cdot R^2_{\text{OS}})_{\text{UF}}$ for each of model = PC (line with circles o), PC-GH (line with triangles △), PF (line with squares □), or PF-GH (line with asterisks *).
Figure 2. Gains in $100 \cdot R^2_{OS}$ from imposing constraint and bagging over UF when $\sigma_u = 1$

Notes: See Figure 1.

Notes: We use the same data set of Campbell and Thompson (2008), which was kindly provided by Sam Thompson. The data frequency is monthly. See subsection 4.1 for details. The PC constraints of CT (2008) for each predictor are shown in column 2. When the sign constraint on the coefficient $\beta$ is negative, the positive constraint PC should be understood as a negative constraint. We do not distinguish the cases in the text for better readability. The term spread (ts) is the long-term minus the short-term Treasury yields. The default spread (ds) is the corporate bond yield minus the Treasury bond yield.
Notes: The reported numbers are out-of-sample statistics $R_{OS}^2$ multiplied by 100, following Campbell and Thompson (2008), as defined in (9). This is to compare seven forecasts in seven columns using each of the 11 predictors (in 11 rows). The last row (row 12) presents the equally-weighted combined-forecast (CF) of the 11 forecasts in each column. $R_{OS}^2$ measures the relative gain of a predictive regression over HA. The numbers in parentheses are the values of statistics to test the null hypothesis that MSFE gain is zero.

Notes: The reported numbers are out-of-sample statistics $R_{OS}^2$ multiplied by 100, of Campbell and Thompson (2008), with the adjustment of Clark and West (2006), as discussed in subsection 4.2.2. As in Table 3, we compare seven forecasts in seven columns using each of the 11 predictors (in 11 rows). The last row (row 12) presents the equally-weighted combined-forecast (CF) of the 11 forecasts in each column. The numbers in parentheses are the values of statistics to test the null hypothesis that MSFE gain with the Clark and West adjustment is zero.

Jin Seo Cho, Isao Ishida and Halbert White

Chapter 2.
Consistent Testing of Functional Form in Time Series Models
James Davidson and Andreea G. Halunga

Chapter 3.
Linearity Testing for Trending Data with an Application of the Wild Bootstrap
Robinson Kruse and Rickard Sandberg

Smooth Transition Models

Chapter 4.
Common Non-linearities in Multiple Series of Stock Market Volatility
Heather M. Anderson and Farshid Vahid

Chapter 5.
Balance Sheet Recessions and Time-Varying Coefficients in a Phillips Curve Relationship: An
Application to Finnish Data
Katarina Juselius and Mikael Juselius

Chapter 6.
Modelling Time-Varying Volatility in Financial Returns: Evidence from Bond Markets
Cristina Amado and Helinä Laakkonen
Model Selection and Econometric Methodology

Chapter 7.
Semi-automatic Non-linear Model Selection
Jennifer L. Castle and David F. Hendry

Chapter 8.
Fundamental Problems with Nonfundamental Shocks
Helmut Lütkepohl

Chapter 9.
Penalized Estimation of Semi-parametric Additive Time Series Models
Marcelo C. Medeiros and Eduardo F. Mendes

Chapter 10.
Oracle Efficient Estimation and Forecasting with the Adaptive Lasso and the Adaptive Group Lasso in Vector Autoregressions
Laurent A. F. Callot and Anders Bredahl Kock

Applied Financial Econometrics

Chapter 11.
Modeling Commodity Prices with Dynamic Conditional Beta
Robert Engle

Chapter 12.
Bias and Uncertainty in Analyst Earnings Expectations at Different Forecast Horizons
Marco Aiolfi, Marius Rodriguez and Allan Timmermann

Chapter 13.
Asymmetric Dependence Patterns in Financial Returns: An Empirical Investigation Using Local Gaussian Correlation
Bård Støve and Dag Tjøstheim

Chapter 14.
Bagging Constrained Equity Premium Predictors
Eric Hillebrand, Tae-Hwy Lee and Marcelo C. Medeiros
List of Contributors

Marco Aiolfi  Quantitative Management LLC
Cristina Amado  Aarhus University and CREATEs, University of Minho and NIPE
Heather M. Anderson  Monash University
Laurent A. F. Callot  Free University Amsterdam and CREATEs
Jennifer L. Castle  Oxford University, Institute for New Economic Thinking, Oxford Martin School
Jin Seo Cho  Yonsei University
James Davidson  University of Exeter Business School
Robert Engle  New York University, Stern School of Business
Andreea G. Halunga  University of Exeter Business School
David F. Hendry  Oxford University, Institute for New Economic Thinking, Oxford Martin School
Eric Hillebrand  Aarhus University and CREATEs
Isao Ishida  Osaka University and CSFI
Katarina Juselius  University of Copenhagen
Mikael Juselius  Bank for International Settlements
Anders Bredahl Kock  Aarhus University and CREATEs
Robinson Kruse  Leibniz University Hannover and CREATEs
Helinä Laakkonen  Bank of Finland
Tae-Hwy Lee  University of California at Riverside
Helmut Lütkepohl  Freie Universität Berlin and DIW
Marcelo C. Medeiros  Pontifical Catholic University of Rio de Janeiro
Eduardo F. Mendes  University of New South Wales
Marius Rodriguez  Federal Reserve Bank of San Francisco
Rickard Sandberg  Stockholm School of Economics
Bård Støve  University of Bergen
Allan Timmermann  University of California, San Diego, Rady School of Management and CREATEs
Dag Tjøstheim  University of Bergen
Farshid Vahid  Monash University
Halbert White  University of San Diego, San Diego
